### ABSTRACT

Face detection and tracking algorithm in real time camera input surroundings is discussed in this paper. Human Face Recognition systems are an identification process in which a person is verified based on human characters. The method described in this paper is very fast with accurate result. The entire face tracking algorithm is allocated into two section. The first section is face detection and second is face tracking. Haar based algorithm is used to detect the face in the image. On the face image to extract feature points, Shi and Thomasi algorithm is used and Pyramidal Lucas-Kanade algorithm is used to track those sensed features. Results on the real time indicate that the proposed algorithm can precisely extract facial features points.

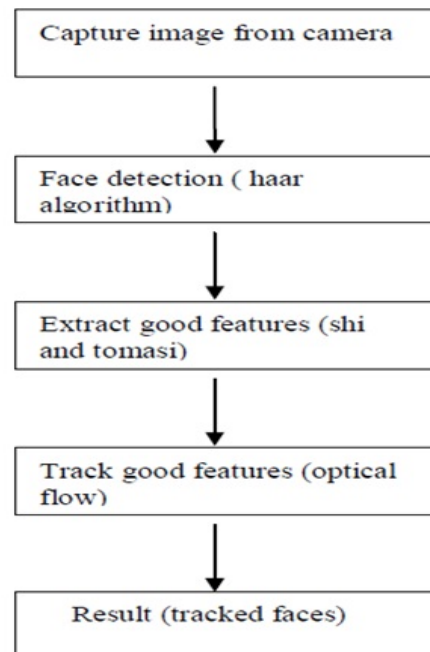

**Keywords:** face detection, tracking, optical flow method, pyramidal lucas-kanade algorithm.

### INTRODUCTION

Facial Features tracking is a vital problem in computer vision due to its wide range of applications in psychological facial expression analysis and human computer interfaces. Recent advances in face video processing and compression have made face-to face communication be practical in real world applications. And after decades, robust and realistic real time face tracking still poses a big challenge. The difficulty lies in a number of issues including the real time face feature tracking under a variety of imaging conditions (e.g., skin color, pose change, self-occlusion and multiple non-rigid features deformation). In this paper, we concentrate our work on facial feature tracking. To detect the face in the image, we have used a face detector based on the Haar-like features [1]. This face detector is fast and robust to any illumination condition. For feature point extraction, we have used Shi and Tomasi method [2]. In order to track the facial feature points, Pyramidal Lucas-Kanade Feature Tracker algorithm [4] is used. Pyramidal Lucas Kanade algorithm [4] is the powerful optical flow algorithm used in tracking. It tracks starting from highest level of an image pyramid and working down to lower levels. Tracking over image pyramids allows large motions to be caught by local windows.

### PROPOSED ALGORITHM

The algorithm used to track the face is explained in this section. The following sections will provide the detail of each step. The algorithm is implemented in C++ language using Opencv Image library.

**Figure-1.** Proposed algorithm to track the face.

### FACE DETECTION

For face detection, we have used Viola & Jones's face detector based on the Haar-like features [1]. In [1], Paul Viola and Michael Jones, describes a visual object detection framework that is capable of processing images extremely rapidly while achieving high detection rates. There are three key contributions. The first contribution is a new a technique for computing a rich set of image features using the integral image. The second is a learning algorithm, based on AdaBoost, which selects a small number of critical visual features and yields extremely efficient classifiers [5]. The third contribution is a method for combining classifiers in a "cascade" which allows background regions of the image to be quickly discarded

while spending more computation on promising object-like regions.

**Feature Selection**

The main purpose of using features rather than the pixels directly is that features can act to encode ad-hoc domain knowledge that is difficult to learn using a finite quantity of training data. Also the the feature-based system operates much faster than a pixel-based system [1]. The simple features used are reminiscent of Haar basis functions which have been used by Papageorgiou *et al.* [6]. Examples of the features used can be seen in Figure-2. The features consist of a number of rectangles that are equal in size and horizontally or vertically adjacent. The value of a two-rectangle feature (A and B in Figure-2) is calculated as the difference between the sum of pixels within the two rectangular regions of the feature. In a three-rectangle feature (C in Figure-2) the sum of pixels in the two outside rectangles is subtracted from the sum of the pixels in the centre rectangle. In a four-rectangle feature (D in Figure-2) the feature value is the difference in sum of pixels between diagonal pairs of rectangles.

**Figure-2.** Rectangle features shown relative to the enclosing detection window.

The sum of the pixels which lie within the white rectangles are subtracted from the sum of pixels in the grey rectangles. Two-rectangle features are shown in (A) and (B). Figure- (C) shows a three-rectangle feature, and (D) a four-rectangle feature.

**Integral Image**

Rectangular features can be computed very rapidly using an intermediate representation for the image called the integral image [1]. The integral image at location (x, y) contains the sum of the pixels above and to the left of (x, y), inclusive:

Using the following pair of recurrences:

$$s(x, y) = s(x, y-1) + i(x, y) \tag{1}$$

$$ii(x, y) = ii(x-1, y) + s(x, y) \tag{2}$$

where  $s(x, y)$  is the cumulative row sum,  $s(x, -1) = 0$  and  $ii(-1, y) = 0$  the integral image can be computed in one pass over the original image [1].

Using the integral image any rectangular sum can be computed in four array references (Figure-3). Clearly the difference between two rectangular sums can be computed in eight references. Since the two rectangle features defined above involve adjacent rectangular sums they can be computed in six array references, eight in the case of the three-rectangle features, and nine for four-rectangle features.

**Figure-3.** Sum of pixel values within “D”.

The Above Figure-3 showing that the sum of the pixels within rectangle D can be computed with four array references. The value of the integral image at location 1 is the sum of the pixels in rectangle A. The value at location 2 is  $A + B$ , at location 3 is  $A + C$ , and at location 4 is  $A + B + C + D$ . The sum within D can be computed as  $4 + 1 - (2 + 3)$ .

**Learning Classification Functions**

Given a feature set and a training set of positive and negative sample images, any number of machine learning approaches could be used to learn a classification function. A variant of AdaBoost is used both to select the features and to train the classifier [5]. In its original form, the AdaBoost learning algorithm is used to boost the classification performance of a simple (sometimes called weak) learning algorithm. Recall that there are over 117,000 rectangle features associated with each image  $24 \times 24$  sub-window, a number far larger than the number of pixels. Even though each feature can be computed very efficiently, computing the complete set is prohibitively expensive. The main challenge is to find a very small number of these features that can be combined to form an effective classifier. In support of this goal, the weak learning algorithm is designed to select the single rectangle feature which best separates the positive and negative examples.

**Cascade of Classifiers**

The overall form of the detection process is that of a degenerate decision tree, what we call a “cascade” [8] (see Figure-4). A positive result from the first classifier triggers the evaluation of a second classifier which has also been adjusted to achieve very high detection rates. A positive result from the second classifier triggers a third

classifier, and so on. A negative outcome at any point leads to the immediate rejection of the sub-window.

A series of classifiers are applied to every sub window. The initial classifier eliminates a large number of negative examples with very little processing. Subsequent layers eliminate additional negatives but require additional computation. After several stages of processing the number of sub windows have been reduced radically. Further processing can take any form such as additional stages of the cascade or an alternative detection system.

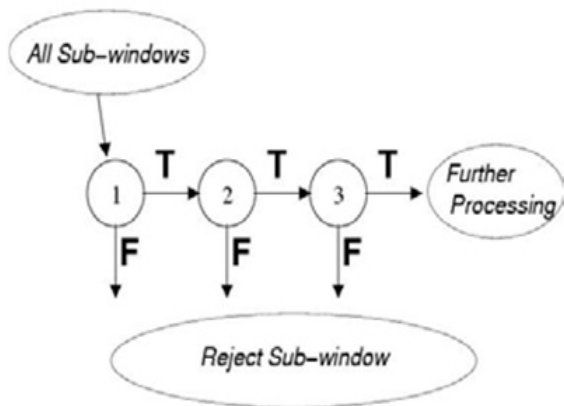

Figure-4. Schematic depiction of a detection cascade.

### FACIAL FEATURE EXTRACTION

For facial feature points extraction we have used Shi and Tomasi method [2]. This method is based on the general assumption that the luminance intensity does not change for image acquisition. To select interest points, a neighbourhood  $N$  of  $n \times n$  pixels is selected around each pixel in the image. The derivatives  $D_x$  and  $D_y$  are calculated with a Sobel operator for all pixels in the block  $N$ . For each pixel the minimum eigenvalue  $\lambda$  is calculated for matrix  $A$  and  $\Sigma$  is performed over the neighborhood of  $N$ . The pixels with the highest values of  $\lambda$  are then selected by thresholding.

The next step is rejecting the corners with the minimal Eigen value less than some threshold. Finally, a test is made, all the found corners are distanced enough from one another by getting two strongest features and checking that the distance between the points is satisfactory. If not, the point is rejected. For further details see [2].

### MOTION DETECTION AND TRACKING

In the field of computer vision motion detection has a relevant importance. By using information contained in a stand image, we can obtain a lot of information about what we are observing, but there is no way to automatically infer what is going to happen in the immediate future. On the other hand a sequence of images provide information about movement of depicted objects. There's a plenty of techniques to recognize movement in a sequence, some based on feature and pattern recognition, some other based just on pixels, regardless what they mean for a human

being. Examples are Block Matching analysis and Optical Flow estimation methods etc.

### Motion and Motion Field

When an object is moving in space in front of a camera there's a corresponding movement on the image surface. Give the point  $P_0$  and its projection  $P_i$ , by knowing its velocity  $V_0$ , we can find out the vector  $V_i$  representing its movement in the image (Figure-5). Given a moving rigid body we can build a motion field by computing all the  $V_i$  motion vectors. The motion field is a way to map the movement in a 3D space, on a 2D image taken on camera: for this reason, since we lose a dimension, we cannot exactly compute motion field, but just approximate it.

Figure-5. Velocity projection over image surface.

### Optical Flow

Optical flow is a phenomenon we deal with every day. It is the apparently visual motion of standing objects as we move through the world. When we are moving the entire world around us seems to move in the opposite way: the faster we move, the faster it does. This motion can also tell us how close we are to the different object we see. The closer they are, the faster their movement will appear. There is also a relationship between the magnitude of their motion and the angle between the direction of our movement and their relative position to us: if we are moving toward an object, it will appear to stand still, but it will become larger as we get closer (this phenomena is also called FOE, focus of expansion); rather, if the object we are looking at is beside us, it will appear moving faster. In computer vision there are a lot of optical flow estimation techniques applied in fields as behaviour recognition or video surveillance; though they are "blinder" than pattern recognition based methods, there are fast enough implementations that allow us to build soft real time applications.

Figure-6. Example of motion flow.

### OPTICAL FLOW TRACKING

Optical flow is the apparent motion of image brightness. Let  $I(x,y,t)$  be the image brightness that changes in time to provide an image sequence. Two main assumptions can be made [9]: 1. Brightness  $I(x,y, t)$  smoothly depends on coordinates  $x, y$  in greater part of the image. 2. Brightness of every point of a moving or static object does not change in time. Let some object in the image, or some point of an object, move and after time  $dt$  the object displacement is  $(dx,dy)$ . Using Taylor series for brightness  $I(x,y,t)$ , gives the following:

$$I(x+dx, y+dy, t+dt) = I(x, y, t) + \frac{\delta I}{\delta x} dx + \frac{\delta I}{\delta y} dy + \frac{\delta I}{\delta t} dt + \dots$$

We have one equation but two variables which means we need some other constraints. For this reason optical flow sometimes doesn't correspond to the motion field. This is the so called aperture problem and we can understand it better by watching at Figure-7, since the cylinder is rotating, if we consider just the black bars, it would be impossible to determine whether they're moving horizontally (as they do), or vertically, as detected by optical flow. It is impossible to determine the real movement unless the end of the bars become visible.

Figure-7. An example when optical flow is different from motion field

### Aperture Problem

One problem we do have to worry about, however, is that we are only able to measure the component of optical flow that is in the direction of the

intensity gradient. We are unable to measure the component tangential to the intensity gradient. This problem is illustrated in figure-8, and further developed below.

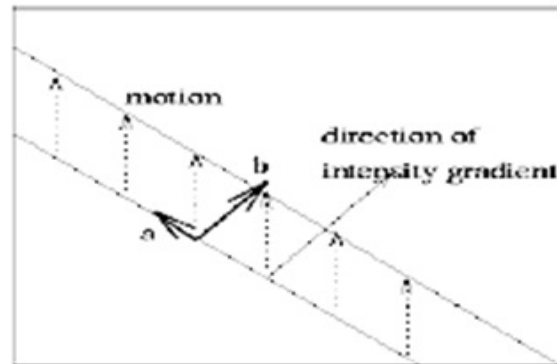

Figure-8. The aperture problem.

Since,

$$I_x u + I_y v + I_t = 0$$

### Optical Flow Methods

There are different methods that add some limit to the problem, in order to estimate the optical flow. Some of them are:

1. **Block based methods** -reducing sum of squared differences or sum of absolute differences, or maximizing normalized cross-correlation
2. **Discrete optimization methods** -the whole space is quantized, and each pixel is labelled, such that the corresponding deformation reduces the distance between the source and the target image. The optimal solution is often calculated through min-cut max-flow algorithms or linear programming.
3. **Differential methods**-The differential methods of optical flow estimation, based on partial spatial and temporal derivatives of the image signal, as following:
  - **Lucas kanade method**-dividing image into patches and calculating a single optical flow on each of them
  - **Horn schunck method**-optimizing a functional based on residuals from the brightness constancy constraint, and a particular regularization term stating the expected smoothness of the flow field.
  - **Buxton buxton method**-centered on a model recovered from the motion of edges in image sequences.
  - **General variational methods**-range of the extensions or alterations of Horn-schunck, using other data terms and other smoothness terms.

Here we are going to explain lucas kanade method.

### Lucas Kanade Method

The Lucas Kanade (LK) algorithm [12], as originally proposed in 1981, was an effort to produce dense results. Yet because the technique is easily applied to a subset of the points in the input image, it has become an important sparse technique. The LK algorithm can be

applied in a sparse context because it depend only on local information that is derived from some small window surrounding each of the points of interest. The disadvantage of using small local windows in Lucas-Kanade is that large motions can move points outside of the local window and thus become difficult for the algorithm to find. This problem led to development of the “pyramidal” Lucas Kanade algorithm [4], which tracks starting from highest level of an image pyramid (lowest detail) and working down to lower levels (finer detail). Tracking over image pyramids allows large motions to be caught by local windows. The basic idea of the LK algorithm rests on three assumptions:

- 1. Brightness constancy**-The pixel intensities of an object do not change between consecutive frames. For grayscale image, this means we assume that the brightness of a pixel does not change as is tracked from frame to frame.
- 2. Temporal persistence or small movements**- No significant displacement between consecutive frames. The image motion of a surface patch changes slowly in time. In practice, this means the temporal increments are fast enough relative to the scale of motion in the image that the object does not move much from frame to frame.
- 3. Spatial coherence**-Neighbouring points in a scene belong to the same surface, have similar motion, and project to nearby points on the image plane.

### Pyramidal Lucas-Kanade Feature Tracker

Pyramidal lucas kanade algorithm is the powerful optical flow algorithm used in feature tracking. Consider an image point  $u = (u_x, u_y)$  on the first image  $I$ , the goal of feature tracking is to find the location  $v = u + d$  in next image  $J$  such as  $I(u)$  and  $J(v)$  are “similar”. Displacement vector  $d$  is the image velocity at  $x$  which also known as optical flow at  $x$  [4]. Because of the aperture problem, it is essential to define the notion of similarity in a 2D neighborhood sense. Let  $\omega_x$  and  $\omega_y$  are two integers. Then  $d$  the vector that minimizes the residual function defined as follows:

$$\epsilon(d) = \epsilon(d_x, d_y) = \sum_{x=u_x-\omega_x}^{u_x+\omega_x} \sum_{y=u_y-\omega_y}^{u_y+\omega_y} (I(x, y) - J(x + d_x, y + d_y))^2$$

Observe that following that definition, the similarity function is measured on a image neighborhood of size  $(2\omega_x + 1) \times (2\omega_y + 1)$ . This neighborhood will be also called integration window. Typical values for  $\omega_x$  and  $\omega_y$  are 2, 3, 4,5,6,7 pixels.

### IMPLEMENTATION AND RESULTS

Program code for the face detection and tracking task is written in CPP language on the Ubuntu-linux platform 12.04 version. OS installed on ODROID board. All the necessary packages and dependencies for the face detection and tracking was successfully installed via internet. All the necessary software tools for secure file transfer and data access between ODROID board and PC was installed.

**Figure-9.** Face detection and tracking results with different poses and angles.

### CONCLUSIONS AND FUTURE WORK

In this paper, face tracking algorithm in real time camera input environment has been examined. To detect the face in the image, we have used a face detector based on the Haar-like features. This face detector is fast and robust to any illumination condition. For feature points extraction, we have used the algorithm of Shi and Tomasi to extract feature points. This method gives good results. To track the facial feature points, Pyramidal Lucas-Kanade Feature Tracker KLT algorithm is used. Using detected points with the algorithm of Shi and Tomasi, we have got good results in video sequence and in real time acquisition. The obtained results indicate that the proposed algorithm can accurately extract facial features points. The future work will include extracting feature points with some conditions to limit the number of feature points in bounding box and choose only the points which describe well the shape of the facial feature. This work will be used for real time facial expression recognition application. Further the work can be extended by detecting faces at different inclinations or slopes as Haar classifier has its own limitations.
